Testing for neglected nonlinearity in time series models

A comparison of neural network methods and alternative tests

Tae-Hwy Lee, Halbert White, and Clive W.J. Granger *

University of California at San Diego, La Jolla, CA 92093, USA

Received March 1990, final version received November 1991

In this paper a new test, the neural network test for neglected nonlinearity, is compared with the Keenan test, the Tsay test, the White dynamic information matrix test, the McLeod–Li test, the Ramsey RESET test, the Brock–Dechert–Scheinkman test, and the Bispectrum test. The neural network test is based on the approximating ability of neural network modeling techniques recently developed by cognitive scientists. This test is a Lagrange multiplier test that statistically determines whether adding 'hidden units' to the linear network would be advantageous. The performance of the tests is compared using a variety of nonlinear artificial series including bilinear, threshold autoregressive, and nonlinear moving average models, and the tests are applied to actual economic time series. The relative performance of the neural network test is encouraging. Our results suggest that it can play a valuable role in evaluating model adequacy. The neural network test has proper size and good power, and many of the economic series tested exhibit potential nonlinearities.

1. Introduction

Specification and estimation of linear time series models are well-established procedures, based on ARIMA univariate models or VAR or VARMAX multivariate models. However, economic theory frequently suggests nonlinear relationships between variables, and many economists appear to believe that the economic system is nonlinear. It is thus interesting to test whether or not a single

* We would like to acknowledge the helpfulness of Tung Liu who allowed us use of his results on the BDS test, and thank the referees and editors for numerous helpful suggestions. We retain responsibility for any remaining errors. White's research was supported by NSF grant SES-8921382.
economic series or group of series appears to be generated by a linear model against the alternative that they are nonlinearly related. There are many tests presently available to do this. This paper considers a 'neural network' test recently proposed by White (1989b), and compares its performance with several alternative tests using a Monte Carlo study.

It is important to be precise about the meaning of the word 'linearity'. Throughout, we focus on a property best described as 'linearity in conditional mean'. Let \( \{Z_t\} \) be a stochastic process, and partition \( Z_t = (y_t, X_t)' \), where (for simplicity) \( y_t \) is a scalar and \( X_t \) is a \( k \times 1 \) vector. \( X_t \) may (but need not necessarily) contain a constant and lagged values of \( y_t \). The process \( \{y_t\} \) is linear in mean conditional on \( X_t \) if

\[
P\left[ E(y_t | X_t) = X_t \theta^* \right] = 1 \text{ for some } \theta^* \in \mathbb{R}^k.
\]

Thus, a process exhibiting autoregressive conditional heteroskedasticity (ARCH) [Engle (1982)] may nevertheless exhibit linearity of this sort because ARCH does not refer to the conditional mean. Our focus is appropriate whenever we are concerned with the adequacy of linear models for forecasting.

The alternative of interest is that \( y_t \) is not linear in mean conditional on \( X_t \), so that

\[
P\left[ E(y_t | X_t) = X_t \theta \right] < 1 \text{ for all } \theta \in \mathbb{R}^k.
\]

When the alternative is true, a linear model is said to suffer from 'neglected nonlinearity'.

Most of the tests treated here have as a first step the extraction of linear structure by the use of an estimated filter. Typically, an AR\((p)\) model is fitted to the series and the test then applied to the estimated residuals. To automate this procedure a particular value of \( p \) is used in the simulations, usually \( p = 1 \) or 2, but when dealing with actual data we shall choose \( p \) using the SIC criterion leading to consistent choice of \( p \) [Hannan (1980)].

Several tests involve regressing linear model residuals on specific functions of \( X_t \), chosen to capture essential features of possible nonlinearities; the null hypothesis is rejected if these functions of \( X_t \) are significantly correlated with the residual. When the null is rejected, the implied alternative model may provide forecasts superior to those from the linear model. These forecasts need not be optimal, merely better. Tests not based on models that imply such forecasts are the McLeod–Li test (based on the autocorrelation of the squared residuals), the Brock–Dechert–Scheinkman test (BDS) (arising from consideration of chaotic processes), and the Bispectrum test. As not all tests are based on alternative forecasting models, we have not considered the relative forecasting abilities of the linear and implied alternative models, although this should be informative and may be considered in further work.
2. The neural network test

Cognitive scientists have recently introduced a class of 'neural network' models inspired by certain features of the way in which information is processed in the brain. An accessible treatment is given by Rumelhart, Hinton, and Williams (1986). A leading model is the 'single hidden layer feedforward network', depicted in fig. 1. In this network, input units ('sensors') send signals $x_i$, $i = 1, \ldots, k$, along links ('connections') that attenuate or amplify the original signals by a factor $\gamma_{ji}$ ('weights' or 'connection strengths'). The intermediate or ‘hidden’ processing unit $j$ ‘sees’ signals $x_i\gamma_{ji}$, $i = 1, \ldots, k$, and processes these in some characteristic, typically simple way. Commonly, the hidden units sum the arriving signals [yielding $\tilde{x}'\gamma_j$, where $\tilde{x} = (1, x_1, \ldots, x_k)'$, $\gamma_j = (\gamma_{j0}, \gamma_{j1}, \ldots, \gamma_{jk})'$] and then produce an output 'activation' $\psi(\tilde{x}'\gamma_j)$, where the 'activation function' $\psi$ is a given nonlinear mapping from $\mathbb{R}$ to $\mathbb{R}$. Often, $\psi$ is a cumulative distribution function (c.d.f.), such as the logistic, $\psi(\lambda) = (1 + e^{-\lambda})^{-1}$, $\lambda \in \mathbb{R}$. Hidden unit signals $\psi(\tilde{x}'\gamma_j), j = 1, \ldots, q$, then pass to the output, which sums what it sees to produce an output

$$f(x, \delta) = \beta_0 + \sum_{j=1}^{q} \beta_j \psi(\tilde{x}'\gamma_j), \quad q \in \mathbb{N},$$

(2.1)

where $\beta_0, \ldots, \beta_q$ are hidden to output weights and $\delta = (\beta_0, \ldots, \beta_q, \gamma_{j0}, \ldots, \gamma_{jk})'$. For convenience and without loss of generality, we suppose that the output unit performs no further transformations.

As discussed by White (1989a, 1990), functions defined by (2.1) belong to a family of flexible functional forms indexed by $\psi$ and $q$. Hornik, Stinchcombe,
and White (1989, 1990) and Stinchcombe and White (1989) – among others – have shown that for wide classes of nonlinear functions $\psi$, functions of the form (2.1) can provide arbitrarily accurate approximations to arbitrary functions in a variety of normed function spaces (e.g., continuous functions on a compact set with the uniform norm, functions in $L_p$ space, and functions in Sobolev spaces with Sobolev norm), provided that $q$ is sufficiently large. Thus, functions of the form (2.1) are capable of approximating an arbitrary nonlinear mapping. Considerable practical experience shows that when the mapping is fairly smooth, tractable values for $q$ can provide quite good approximations. For example, Lapedes and Farber (1987) well approximated the deterministic chaos of the logistic map using five hidden units, while Gallant and White (1992) well approximated the Mackey–Glass chaos with five hidden units.

Similar approximation-theoretic issues arise in the context of projection pursuit [Friedman and Stuetzle (1981), Diaconis and Shahshahani (1984), Huber (1985), Jones (1991)]. In fact, (2.1) can be viewed as a restricted projection pursuit function in which the functions $\psi$ are given a priori. In standard projection pursuit, $\psi$ may differ for each term (replace $\psi$ with $\psi_j$) and one must estimate the $\psi_j$.

The neural network test for neglected nonlinearity uses a single hidden layer network augmented by connections from input to output. Network output $o$ is then

$$o = \bar{x}'\theta + \sum_{j=1}^{q} \beta_j \psi(\bar{x}'\gamma_j).$$

When the null hypothesis of linearity is true, i.e.,

$$H_0: \quad P[\mathbb{E}(y_i|X_i) = \bar{X}_i\theta^*] = 1 \quad \text{for some } \theta^*,$$

then optimal network weights $\beta_j$, say $\beta_j^*$, are zero, $j = 1, \ldots, q$, yielding an ‘affine network’. The neural network test for neglected nonlinearity tests the hypothesis $\beta_j^* = 0$, $j = 1, \ldots, q$, for particular choice of $q$ and $\gamma_j$. The test will have power whenever $\sum_{j=1}^{q} \beta_j \psi(\bar{x}'\gamma_j)$ is capable of extracting structure from $e_i^* = y_i - \bar{X}_i\theta^*$. [Under the alternative, $\theta^*$ is the parameter vector of the optimal linear least squares approximation to $\mathbb{E}(y_i|X_i)$.] Recent theoretical work of Stinchcombe and White (1991) suggests that when $\psi$ is the logistic c.d.f., the terms $\psi(\bar{x}'\gamma_j)$ are generically (in $\gamma_j$) able to extract such structure.

Implementing the test as a Lagrange multiplier test leads to testing

$$H_0': \quad \mathbb{E}(\Psi_t e_t^*) = 0 \quad \text{vs} \quad H_1': \quad \mathbb{E}(\Psi_t e_t^*) \neq 0,$$

where $\Psi_t = (\psi(\bar{X}_1; \Gamma_1), \ldots, \psi(\bar{X}_q; \Gamma_q))'$, and $\Gamma = (\Gamma_1, \ldots, \Gamma_q)$ is chosen a priori, independently of the random sequence $\{X_i\}$, for given $q \in \mathbb{N}$. We call $\Psi_t$ the ‘phantom hidden unit activations’. As in Bierens (1987) and Bierens and Hartog (1988), we shall choose $\Gamma$ at random. An analysis for $\Gamma$ chosen to maximize
departures of \( E(Y, e) \) from zero (with \( q = 1 \), say) can be carried out along the lines of Bierens (1990), but is beyond the scope of the present work.

In constructing the test, we replace \( e \) with estimated residuals \( \hat{e}_t = y_t - \hat{X}_t \hat{\theta} \), with \( \hat{\theta} \) obtained by least squares. This leads to a statistic of the form

\[
M_n = \left( n^{-1/2} \sum_{t=1}^{n} \Psi_t \hat{e}_t \right)^T \hat{W}_n^{-1} \left( n^{-1/2} \sum_{t=1}^{n} \Psi_t \hat{e}_t \right),
\]

where \( \hat{W}_n \) is a consistent estimator of \( W^* = \text{var}(n^{-1/2} \sum_{t=1}^{n} \Psi_t e^*_t) \). Standard asymptotic arguments lead to the conclusion \( M_n \xrightarrow{d} \chi^2(q) \) as \( n \to \infty \) under \( H_0 \).

Two practical difficulties may be noted: 1) Elements of \( Y_t \) tend to be collinear with \( X_t \) and with themselves. 2) Computation of \( \hat{W}_n \) can be tedious. These can be remedied by 1) conducting the test using \( q^* < q \) principal components of \( Y_t \), not collinear with \( X_t \), denoted \( \Psi_t^* \), and 2) using an equivalent test statistic that avoids explicit computation of \( \hat{W}_n \).

\[
nR^2 \xrightarrow{d} \chi^2(q^*),
\]

where \( R^2 \) is the uncentered squared multiple correlation from a standard linear regression of \( \hat{e}_t \) on \( \Psi_t^*, \hat{X}_t \).

3. Alternative tests

In every case an AR(\( p \)) model is first fitted to the data and nonlinearity tested for the residuals. In fact any linear model could first be used.

3.1. The Keenun, Tsay, and Ramsey RESET tests

Let \( y_t \) be series of interest and let \( X_t = (y_{t-1}, \ldots, y_{t-p})' \) be used to explain \( y_t \). (An obvious generalization allows \( X_t \) to include other explanatory variables.) In performing the tests, \( p \) and any other contents of \( X_t \) have to be determined by the user.

The first step of these tests is linear regression of \( y_t \) on \( \hat{X}_t \), producing an estimate \( \hat{\theta} \), a forecast \( \hat{f}_t = \hat{X}_t \hat{\theta} \), and estimated residuals \( \hat{e}_t = y_t - \hat{X}_t \hat{\theta} \).

Keenan (1985) introduced a test based on the correlation of \( \hat{e}_t \) with \( f_t^2 \). The Keenan test essentially asks if the squared forecast has any additional forecasting ability, and so tests directly for departures from linearity in mean.

The test of Tsay (1986) has a similar form to the Keenan test, but tests the possibility of improving forecasts by including \( p(p+1)/2 \) cross-product terms of the components of \( X_t \), of the form \( y_{t-j}y_{t-k}, k \geq j, j, k = 1, \ldots, p \). The test is again directly designed to test for departures from linearity in mean.
The RESET test proposed by Ramsey (1969) generalizes the Keenan test in a different way. Using the polynomials in \( f_i \), we can postulate an alternative model of the form

\[
y_t = \tilde{X}_i \theta + a_2 f_i^2 + \cdots + a_k f_i^k + v_t \quad \text{for some} \quad k \geq 2.
\]

The null hypothesis is \( H_0: a_2 = \cdots = a_k = 0 \). Denoting \( \hat{e} = (\hat{e}_1, \ldots, \hat{e}_n)' \) and \( \hat{v} = (\hat{v}_1, \ldots, \hat{v}_n)' \), the test statistic is

\[
\text{RESET} = \left( \frac{(\hat{e}' \hat{e} - \hat{v}' \hat{v})}{(k - 1)} \right) / \left( \frac{\hat{v}' \hat{v}}{(n - k)} \right),
\]

which is approximately \( F(k - 1, n - k) \) when \( H_0 \) is true.

As for the neural network tests, collinearity can be avoided by forming the principal components of \( (f_i^2, \ldots, f_i^k) \), choosing the \( p^* < (k - 1) \) largest (except the first principal component so as not to be collinear with \( \tilde{X}_i \)), and then regressing \( y_t \) on these and \( \tilde{X}_i \), giving the residual \( \hat{u}_t \). The test statistic is

\[
\text{RESET1} = \left( \frac{\hat{e}' \hat{e}}{p^*} \right) / \left( \frac{\hat{u}_t' \hat{u}_t}{n - k} \right),
\]

which is \( F(p^*, n - k) \) when \( H_0 \) is true.

A Lagrange multiplier version of the test is obtained by regressing \( \hat{u}_t \) on \( \tilde{X}_i \) and \( f_i^2, \ldots, f_i^k \) to get an \( R^2 \) statistic. Under regularity conditions \( nR^2 \) is asymptotically distributed as \( \chi^2(k - 1) \) under the null. Again, forming the principal components of \( (f_i^2, \ldots, f_i^k) \), choosing the \( p^* \) largest, and then regressing \( \hat{e}_t \) on these and \( \tilde{X}_i \), also gives an \( R^2 \) statistic. Under regularity conditions, the statistic \( \text{RESET2} = nR^2 \) is distributed as \( \chi^2(p^*) \) for \( n \) large, under \( H_0 \). For this test both \( k \) and \( p^* \) have to be selected by the user. The RESET tests are sensitive primarily to departures from linearity in mean.

3.2. The White dynamic information matrix test

White (1987, 1992) proposed a specification test for dynamic (time series) models, based on the covariance of conditional score functions. For the normal linear model

\[
y_t = \tilde{X}_i \theta + e_t, \quad e_t \sim N(0, \sigma^2),
\]

the log-likelihood is

\[
\log L(x_t, \theta, \sigma) = \text{constant} - \log \sigma - (y_t - \tilde{X}_i \theta)^2 / 2\sigma^2.
\]

With \( u_t = (y_t - \tilde{X}_i \theta) / \sigma \), the conditional score function is

\[
s_t(X_t, \theta, \sigma) = \nabla \log f_t(X_t, \theta, \sigma) = \sigma^{-1} (u_t, u_t X_t, u_t^2 - 1)',
\]

where \( \nabla \) is the gradient operator with respect to \( \theta \) and \( \sigma \). Denoting \( s_t^* = s_t(X_t, \theta^*, \sigma^*) \), correct specification implies \( E(s_t^*) = 0 \) and \( E(s_t^* s_t'^*) = 0 \), \( t = 1, 2, \ldots, \tau = 1, \ldots, t \). The dynamic information matrix test can be based on the indicator \( m_t = S \text{ vec } s_t s_{t-1}' \), where \( S \) is a nonstochastic selection matrix focusing attention on particular forms of possible misspecification.
Denoting \( \hat{s}_t = s_t(X_t, \hat{\theta}, \hat{\sigma}) \) and \( \hat{m}_t = S \text{ vec } \hat{s}_t, \hat{s}_{t-1} \), where \( \hat{\theta} \) and \( \hat{\sigma} \) are the quasi-maximum likelihood estimators (QMLEs), the following versions of the test statistic can be formed: 1) \( \text{WHITE}_1 = n \hat{\mu}_n^2 \hat{J}_n^{-1} \hat{\mu}_n \) where \( \hat{\mu}_n = n^{-1} \sum_{t=1}^n \hat{m}_t \), \( \hat{J}_n = n^{-1} \sum \hat{m}_t \hat{m}_t' - (n^{-1} \sum \hat{m}_t \hat{s}_t') \hat{s}_t [n^{-1} \sum \hat{m}_t \hat{s}_t']^{-1} (n^{-1} \sum \hat{m}_t \hat{s}_t') \); 2) \( \text{WHITE}_2 = n R^2 \), where \( R^2 \) is the (constant unadjusted) squared multiple correlation coefficient of the regression of the constant unity on the explanatory variables \( \hat{m}_t, \hat{s}_t \); 3) \( \text{WHITE}_3 = n R^2 \) where \( R^2 \) is the (constant unadjusted) squared multiple correlation coefficient from the regression of \( \hat{u}_t = (y_t - \hat{X}_t, \hat{\theta})/\hat{\sigma} \) on \( \hat{X}_t \) and \( \hat{k}_t \), with \( \hat{k}_t \) being defined from \( \hat{m}_t = \hat{k}_t \hat{u}_t \). Under \( H_0 \), \( \text{WHITE}_1, \text{WHITE}_2, \) and \( \text{WHITE}_3 \) all have the \( \chi^2(q) \) distribution asymptotically, where \( q \) is the dimension of \( m_t \). These tests will be sensitive to departures from linearity in mean to the extent that these departures induce autocorrelation in \( s_t^* \). Other misspecifications resulting in such autocorrelations will also be detected.

3.3. The McLeod and Li test

It was noted in Granger and Andersen (1978) that for a linear stationary process

\[
\text{corr}(y_t^2, y_{t-k}^2) = [\text{corr}(y_t, y_{t-k})]^2 \quad \text{for all } k,
\]

and so departures from this would indicate nonlinearity. McLeod and Li (1983) use the squared residuals from a linear model and apply a standard Box–Ljung Portmanteau test for serial correlation. This test is sensitive to departures from linearity in mean that result in apparent ARCH structure; ARCH itself will also be detected.

3.4. The BDS test

Whilst conducting research on tests for chaos, Brock, Dechter, and Scheinkman (1986) derived a test appropriate for detecting general stochastic nonlinearity. For a series \( y_t \), define

\[
C_m(\varepsilon) = n^{-2} \text{[number of pairs (i,j) such that ]}
\]

\[
|y_i - y_j| < \varepsilon, |y_{i+1} - y_{j+1}| < \varepsilon, \ldots, |y_{i+m-1} - y_{j+m-1}| < \varepsilon,
\]

so that \( y_i, \ldots, y_{i+m-1} \) and \( y_j, \ldots, y_{j+m-1} \) are two segments of the series of length \( m \), such that all corresponding pairs of points differ from each other by size \( \varepsilon \).

The test statistic is \( \text{BDS} = n^{1/2} [C_m(\varepsilon) - C_1(\varepsilon)^m] \). Under the null hypothesis that the series is independently and identically distributed, BDS is asymptotically normally distributed with zero mean and a known complicated variance. The test is interesting because it arises from very different
considerations than the others. For our implementation, \( y_t \) is replaced by the linear model estimated residuals. The BDS test will be sensitive to departures from linearity in mean, but may also have power against series linear in mean with ARCH.

3.5. The Bispectrum test

Following earlier work by Subba Rao and Gabr (1980, 1984), a test based on the bispectrum was suggested by Hinich (1982) and Ashley, Patterson, and Hinich (1986). If \( \{ y_t \} \) is a zero mean stationary series, it can be expressed as

\[
y_t = \sum_{i=0}^{\infty} a_i e_{t-i},
\]

where \( \{ e_t \} \) is purely random and the weights \( \{ a_i \} \) are fixed. Define the second- and third-order autocovariances by

\[
c(h) = \mathbb{E}[y_{t+h} y_t]
\]

and

\[
c(h, k) = \mathbb{E}[y_{t+h} y_{t+k} y_t],
\]

and write their corresponding Fourier transforms (the power spectrum and power bispectrum) as

\[
S(\omega) = \frac{1}{2\pi} \int c(h) \exp(-2\pi i \omega h) \, dh,
\]

\[
B(\omega_1, \omega_2) = \frac{1}{2\pi} \int c(h, k) \exp(-2\pi i (\omega_1 h + \omega_2 k)) \, dh \, dk.
\]

It can be shown that

\[
\frac{|B(\omega_1, \omega_2)|^2}{S(\omega_1)S(\omega_2)S(\omega_1 + \omega_2)} = \frac{\mu_3^2}{\sigma^4}
\]

for all \( (\omega_1, \omega_2) \). The square root of this is called the skewness of \( \{ y_t \} \). The fact that the skewness of such a time series is independent of \( (\omega_1, \omega_2) \) is used to test nonlinearity. The test statistic of Hinich (1982) is based on the interquartile range of the estimated ratio of the skewness over a set of frequency pairs, \( (\omega_1, \omega_2) \). This proved to be too expensive to use in the Monte Carlo simulation but was used in section 6. We thank the authors of this test for providing the software to perform the test. In our implementation \( y_t \) is again replaced by the linear model estimated residual. The Bispectrum test is sensitive to departures from linearity in mean, but will also detect ARCH.

4. The simulation design

Two blocks of univariate series were generated from models chosen to represent a variety of stable nonlinear situations. Throughout \( e_t \sim \mathcal{N}(0, 1) \) is a white noise series.

4.1. Block 1

(i) Autoregressive (AR)

\[
y_t = 0.6 y_{t-1} + e_t,
\]

a representative linear model.
(ii) **Bilinear (BL)**

\[ y_t = 0.7 y_{t-1} \varepsilon_{t-2} + \varepsilon_t, \]

a bilinear model having the same covariance properties as a white noise; see Granger and Andersen (1978).

(iii) **Threshold autoregressive (TAR)**

\[ y_t = \begin{cases} 
0.9 y_{t-1} + \varepsilon_t & \text{for } |y_{t-1}| \leq 1, \\
-0.3 y_{t-1} + \varepsilon_t & \text{for } |y_{t-1}| > 1, 
\end{cases} \]

an example considered by Tong (1983).

(iv) **Sign autoregressive (SGN)**

\[ y_t = \text{sgn}(y_{t-1}) + \varepsilon_t, \]

where \( \text{sgn}(x) = 1 \) if \( x > 0 \), \( = 0 \) if \( x = 0 \), \( = -1 \) if \( x < 0 \). This is a particular form of nonlinear autoregression (NLAR).

(v) **Nonlinear autoregressive (NAR)**

\[ y_t = \frac{(0.7|y_{t-1}|)}{|y_{t-1}| + 2} + \varepsilon_t, \]

another NLAR model, closely related to a class of models known as rational NLAR.

The models of the second block have been used in previous papers on nonlinear testing, particularly by Keenan (1985), Tsay (1986), Ashley, Patterson and Hinich (1986), and Chan and Tong (1986), and so are included to allow comparison with these studies.

4.2. **Block2**

(1) **MA(2) (Model1)**

\[ y_t = \varepsilon_t - 0.4 \varepsilon_{t-1} + 0.3 \varepsilon_{t-2}. \]

(2) **Heteroskedastic MA(2) (Model2)**

\[ y_t = \varepsilon_t - 0.4 \varepsilon_{t-1} + 0.3 \varepsilon_{t-2} + 0.5 \varepsilon_t \varepsilon_{t-2}, \]

where the forecastable part of \( y_t \) is linear and the final product term introduces heteroskedasticity.
(3) Nonlinear MA (Model3)

\[ y_t = \varepsilon_t - 0.3 \varepsilon_{t-1} + 0.2 \varepsilon_{t-2} + 0.4 \varepsilon_{t-1} \varepsilon_{t-2} - 0.25 \varepsilon_{t-2}^2, \]

where the final two terms give a nonlinear MA model that is typically noninvertible.

(4) AR(2) (Model4)

\[ y_t = 0.4 y_{t-1} - 0.3 y_{t-2} + \varepsilon_t, \]

a stationary linear AR model.

(5) Bilinear AR (Model5)

\[ y_t = 0.4 y_{t-1} - 0.3 y_{t-2} + 0.5 y_{t-1} \varepsilon_{t-1} + \varepsilon_t, \]

a model containing both linear and bilinear terms.

(6) Bilinear ARMA (Model6)

\[ y_t = 0.4 y_{t-1} - 0.3 y_{t-2} + 0.5 y_{t-1} \varepsilon_{t-1} + 0.8 \varepsilon_{t-1} + \varepsilon_t. \]

It is seen that three linear models are included for purposes of comparison. Data were generated with sample sizes 50, 100, and 200. 1000 replications were used to obtain estimates of power. In a few sample cases the plot of \( y_t \) against \( y_{t-1} \) was constructed. It was generally true that there was no obvious nonlinearity visible, except possibly for the SGN autoregressive series.

All of the tests can be generalized in fairly obvious ways to consider nonlinear relationships between pairs of series. As part of an initial exploration of this situation, two nonlinearly related pairs of series were also generated.

4.3. Bivariate models

SQ

\[ y_t = x_t^2 + \varepsilon_t, \]

EXP

\[ y_t = \exp(x_t) + \varepsilon_t, \]
where $x_t = 0.6x_{t-1} + e_t$, $e_t$ and $e_t$ are independent, $e_t \sim N(0, \nu)$ and $e_t \sim N(0, 1)$ white noises. Three different values for the variance of $e_t$ were used, $\nu = 1, 25, 400$. Plots of $y_t$ against $x_t$ with $\nu = 1$ clearly showed a nonlinear relationship, but this was no longer clear when $\nu = 400$.

For all the simulations except for TSAY2, the information set is $X_t = y_{t-1}$ for Block 1, $X_t = (y_{t-1}, y_{t-2})'$ for Block 2, and $X_t = x_t$ for the bivariate models. For the TSAY2 test, $X_t = (y_{t-1}, y_{t-2}, y_{t-3}, y_{t-4}, y_{t-5})'$ for Block 1 and Block 2 and $X_t = (x_{t-1}, x_{t-2}, x_{t-3}, x_{t-4})'$ for bivariate models.

In performing neural network tests the logistic c.d.f. $\psi(\lambda) = \left[1 + \exp(-\lambda)\right]^{-1}$ is used. The input to hidden unit weights $\Gamma_{ji}$ were randomly generated from the uniform distribution on $[-2, 2]$. The variables $y_t$, $X_t$ have been resealed onto $[0, 1]$. We choose $q = 10$ for NEURAL1 and $q = 20$ for NEURAL2. We use $q^* = 2$ largest principal components (excluding the first principal component) for the Block 1 and bivariate models and $q^* = 3$ for the Block 2 models.

For the White dynamic information matrix tests, appropriate choice of $S$ gives

$$m_t = \sigma^{-2}(u_t u_{t-1}, X_t u_t, u_{t-1}, X_t X_{t-1} u_t u_{t-1}),$$

where $X_t = y_{t-1}$ for Block 1, $X_t = (y_{t-1}, y_{t-2})'$ for Block 2, and $X_t = x_t$ for the bivariate models, so that $q = 4$ for the Block 1 and bivariate models and $q = 8$ for the Block 2 models.

We choose 20 degrees of freedom for the McLeod and Li tests, and $k = 5$, $p^* = 1$ in RESET1 and RESET2 for every model.

### 5. Results of the simulation

Critical values for the various tests were constructed using both the asymptotic theory and by simulation using a linear model. For Block 1 the AR(1) (Model (i)) was used and for Block 2 the AR(2) (Model 4) was used, for sample sizes 50, 100, and 200, and with 6000 replications. The bivariate models used the AR(1) values. 10%, 5%, 2.5%, and 1% critical values were constructed for each test, but to conserve space only 5% values are reported.

Tables 1 and 2 show the 5% critical values simulated for sample sizes 50, 100, and 200, and the asymptotic values.

Table 3 illustrates the stability of the 5% critical values using 6000 simulations. 5% critical values were obtained from each of the AR(1) models $x_t = \phi x_{t-1} + e_t$, with $\phi$ taking the values 0.9, 0.6, 0.3, 0.0, 0.3, 0.6, and 0.9, for sample size $n = 100$. Again, with this sample size, 1000 replications of the AR(1) model with $\phi = 0.6$ were constructed, and the tests applied with the critical values obtained from the previous simulation. The ‘power’ or percent

*The first number in each cell is the simulated critical value from AR(1), $y_t = 0.6y_{t-1} + \varepsilon_t$, with 6000 replications, and the second number in parentheses is the asymptotic critical value.

rejection in each case is shown in table 3. Thus the figure 4.2 at the top left means that data from an AR(1) with $\phi = 0.6$ led to rejection of the linearity null hypothesis on 4.2% of occasions by the NEURAL1 test using the critical value obtained from the AR(1) model with $\phi = -0.9$. With 1000 replications, the 95% confidence intervals of these powers (sizes) around the hoped for value of 5%, is 3.6 to 6.4%. The final column shows the rejection percentage of $H_0$ using the asymptotic 5% critical values. Virtually all of the neural network test results lie in the 95% confidence interval for size, as do all of the values in the column when $\phi = 0.6$. However, some tests do not perform satisfactorily, particularly the KEENAN, TSAY1, TSAY2, and WHITE1 tests, suggesting either that the critical values are not stable across simulation models or that the asymptotic theory is not appropriate with a sample size of 100. Because of its complexity, the BDS test was not calculated in this particular exercise.

* (1) Each column shows the power (%) for AR(1) \( y_t = 0.6y_{t-1} + \varepsilon_t\), using the 5% critical values simulated with \( y_t = \phi y_{t-1} + \varepsilon_t, \phi = -0.9, -0.6, -0.3, 0.0, 0.3, 0.6, 0.9\). The last column shows the power for the AR(1) using 5% asymptotic critical values. (2) 95% confidence interval of the observed size is (3.6, 6.4), since if the true size is \( s \) the observed size follows the (asymptotic) normal distribution with mean \( s \) and variance \( s(1-s)/1000 \). (3) Sample size = 100, replications = 1000.
Table 4 shows the power of the tests using the Block1 models plus the bivariate models with \( v = 1 \) and with sample size \( n = 200 \). The first number is the power using the 5% critical value from the simulation of the AR(1) model with \( \phi = 0.6 \) and below it, in parentheses, is the power using the 5% theoretical critical value. A great deal of variation in the power of the tests is observed. Most tests have reasonable power for the bilinear model, but the White dynamic information matrix test and McLeod–Li test are particularly successful. For the threshold autoregressive data, only the neural network test has any success and similarly for the SGN autoregressive model, where the neural network test is very powerful, the RESET test has some power, and the other tests have very

* Power using 5% critical value simulated with AR(1) model is shown (except for BDS test), and power using 5% asymptotic critical value is shown in parentheses. Sample size = 200, replications = 1000. The results for BDS test in Liu (1990) with embedding dimension \( m = 2 \) and \( \epsilon = (0.8)^6 \) are reported here. The series were divided by the range of the data before applying the BDS tests.
little power. The particular nonlinear AR model used (NAR) is difficult to detect, as the power is low for all the tests. The bivariate cases are discussed later.

Table 5 shows similar power results (5% critical value, \( n = 200 \)) for the Block2 series. To provide the simulation critical values, 6000 simulations of Model4, an AR(2) model, were generated. 1000 replications for each of the six models were generated, and the simulated and asymptotic 5% critical values were used to obtain estimated powers. Model1 is linear, being an MA(2), and most tests reject the null near the correct 5% rate, but the WHITE tests reject frequently, indicating dynamic misspecification, as an MA(2) is only poorly approximated by an AR(2) model. All of the tests have good power against the bilinear models.

* Power using 5% simulated critical values is shown. Replications = 1000, sample size n = 50, 100, 200.
and the nonlinear moving average model (Model3), but little power against the heteroskedastic MA model (Model2).

Similar tables were constructed for sample sizes 50 and 100 but are not shown in full detail. Tables 6 and 7 show power against sample size for four of the tests, NEURAL1, TSAY1, WHITE3, and RESET2. The results are generally as expected, with power increasing as sample size increases for most of the nonlinear models.

From these results and others not shown some general comments can be made:

(i) NEURAL1 and NEURAL2 are virtually the same; thus the extra work for NEURAL2 is probably not worthwhile.

(ii) TSAY1 and TSAY2 both have nuisance parameter problems; TSAY1 seems to be better.

(iii) The WHITE tests all have nuisance parameter problems; WHITE3 is generally better.

(iv) RESET1 and RESET2 are virtually identical, RESET2 being marginally better.

(v) The McLeod–Li test is generally weak compared to the alternatives.

(vi) The TSAY1 test is virtually always more powerful than the KEENAN test.

(vii) The BDS test is good with bilinear data and has average power in other cases.

(viii) No single test was uniformly superior to the others.

Table 8 shows the power of four tests in the bivariate case \( y_t = x_t^2 + \varepsilon_t \), \( \varepsilon_t \sim N(0, \sigma^2) \), where \( x_t = 0.6x_{t-1} + \varepsilon_t \), \( \varepsilon_t \sim N(0, 1) \). The three values of \( \sigma \) chosen were 1, 5, and 20, corresponding to approximate signal-to-noise ratios:

<table>
<thead>
<tr>
<th>( \sigma )</th>
<th>1</th>
<th>5</th>
<th>20</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \text{var}(x^2)/\text{var}(\varepsilon) )</td>
<td>7.0</td>
<td>0.28</td>
<td>0.019</td>
</tr>
</tbody>
</table>

Not all situations were simulated. The NEURAL1 and TSAY1 tests are quite powerful in most situations, and have some power even with signal-to-noise ratios around 2% (corresponding to \( \sigma = 20 \)).

Table 9 shows the same information for the bivariate model \( y_t = \exp(x_t) + \varepsilon_t \), \( \varepsilon_t \sim N(0, \sigma^2) \), where \( x_t \) is as before and the same set of \( \sigma \) values are used. The signal-to-noise ratios are:

<table>
<thead>
<tr>

The results are similar to the previous case. It is encouraging that the NEURAL and TSAY tests have such good power in many cases.

6. Tests on actual economic time series

To illustrate the behavior of the various tests for actual economic time series, five economic series were analyzed. The series were first transformed to produce stationary sequences. If \( z_t \) is the original series, \( y_t = \Delta z_t \) or \( y_t = \Delta \log z_t \) is fitted by \( \text{AR}(p) \), where \( p \) is determined by the SIC criterion [Sawa (1978) Hannan (1980)]. Thus \( X_t = (y_{t-1}, \ldots, y_{t-p})' \). For the moment, we assume the absence of ARCH effects. We discuss the consequences of ARCH below.

Table 10 shows asymptotic \( p \)-values for the various tests; a low \( p \)-value suggests rejection of the null. As the neural network test involves randomly selecting the \( \Gamma \) parameters, it can be repeated several times with different draws. We obtain \( p \)-values for several draws of the neural network test, but these are not independent. Despite dependence, the Bonferroni inequality provides an upper bound on the \( p \)-value. Let \( P_1, \ldots, P_m \) be \( p \)-values corresponding to \( m \) test

* (1) US/Japan exchange rate, \( y_t = \Delta \log z_t \), AR(1), 1974:1–1990:7, monthly, 199 observations; (2) US three-month T-bill interest rate, \( y_t = \Delta z_t \), AR(6); (3) US M2 money stock, \( y_t = \Delta \log z_t \), AR(1); (4) US personal income, \( y_t = \Delta \log z_t \), AR(1); (5) US unemployment rate, \( y_t = \Delta z_t \), AR(4). Series (2), (3), (4), and (5) are monthly for 1959:1–1990:7 with 379 observations. Series (1) and (2) are not seasonally adjusted while the others are. BDS test: embedding dimension \( m = 2, \epsilon = (0.8)^3 \).
statistics, and $P_{(1)}, \ldots, P_{(m)}$ the ordered $p$-values. The Bonferroni inequality leads to rejection of $H_0$ at the $\alpha$ level if $P_{(1)} \leq \alpha/m$, so $\alpha = mP_{(1)}$ is the Bonferroni bound. A disadvantage of this simple procedure is that it is based only on the smallest $p$-value, and so may be too conservative. Holm (1979), Simes (1986), Hommel (1988, 1989), and Hochberg (1988) discuss improved Bonferroni procedures. Hochberg's modification is used here, defined by the rule 'reject $H_0$ at the $\alpha$ level if there exists a $j$ such that $P_{(j)} \leq \alpha/(m - j + 1)$, $j = 1, \ldots, m'$. The improved Bonferroni bound is $\alpha = \min_{j=1, \ldots, m}(m - j + 1)P_{(j)}$.

In table 10, $m = 5$ neural network tests are conducted for each series. Both simple and Hochberg Bonferroni bounds are reported. These results illustrate a cautionary feature of the neural network test, as quite different $p$-values are found for different draws. Thus, if one had relied on a single use of the test, quite different conclusions would be possible, just as would be true if one relied on single but different standard tests for nonlinearity. Use of Bonferroni procedures with multiple draws of the neural network test appears to provide useful insurance against using a single test that by chance looks in the wrong direction.

Although the results illustrate application of several tests for neglected nonlinearity to various economic time series, we must strongly emphasize that they do not by themselves provide definitive evidence of neglected nonlinearity in mean. The reason is that, unlike the situation found in our simulations, we cannot be sure that there are not other features of the series studied that lead to the observed results; in particular, the possible presence of ARCH effects cannot be ruled out.

Generally, ARCH will have one of two effects: either it will cause the size of the test to be incorrect while still resulting in a test statistic bounded in probability under the null (as for the neural network, KEENAN, TSAY, WHITE, and RESET tests), or it will directly lead (asymptotically) to rejection despite linearity in mean (as with the McLeod and Li, BDS, and Bispectrum tests). Two remedies suggest themselves: one may either (1) remove the effect of ARCH, or (2) remove ARCH. The first is relevant to tests with adversely affected size. The effect of ARCH can be removed using a heteroskedasticity-consistent covariance matrix estimator in computing the various test statistics. The approach of Wooldridge (1990) may prove especially useful. The second approach is possible whenever one is confidently able to specify the form of the ARCH effect. However, use of a misspecified ARCH model in the procedure will again adversely affect the size of the test. Furthermore, if the alternative is true, the fitted ARCH model can be expected to absorb some or perhaps even much of the neglected nonlinearity. Conceivably, this could have adverse impact on the power of the procedure. Consideration of either of these remedies raises issues that take us well beyond the scope of the present study; their investigation is left to other work.
Thus, we can take the empirical results of this section as indicating that either neglected nonlinearity or ARCH may be present in series (1)–(5), but that further investigation is needed. The results of this paper are only a first step on the way to analyzing methods capable of unambiguous detection of neglected nonlinearity in real-world settings.

7. Conclusions

As with any Monte Carlo study, results obtained can be considerably influenced by the design of the experiment, in this case the choice of nonlinear models and choices made in constructing the test studied. Assuming that the models chosen are of general interest, we have found that several of the tests studied here have good power against a variety of alternatives, but no one of these tests dominates all others. The new neural network test considered in this paper appears to perform as well as or better than standard tests in certain contexts. Application of the tests studied here to actual economic time series suggests the possible presence of neglected nonlinearity, but further investigation is needed to separate out possible effects of ARCH.
